**Abstract.** Modular extensibility is a highly desirable property of a domain-specific language (DSL): the ability to add new features without affecting the implementation of existing features. Functional mixins (also known as open recursion) are highly suitable for this purpose.

We study the use of mixins in Haskell for a modular DSL for search heuristics used in systematic solvers for combinatorial problems, that generate optimized C++ code from a high-level specification. We show how to apply memoization techniques to tackle performance issues and code explosion due to the highly recursive nature of the mixins.

As such heuristics are conventionally implemented as highly entangled imperative algorithms, our Haskell mixins are monadic. Memoization of monadic components causes further complications for us to deal with.

## 1 Introduction

Search heuristics often make all the difference between effectively solving a combinatorial problem and utter failure. Heuristics enable a search algorithm to become efficient for a variety of reasons, e.g., incorporation of domain knowledge, or randomization to avoid heavy tailed runtimes. Hence, the ability to swiftly design search heuristics that are tailored towards a problem domain is essential to performance improvement. In other words, this calls for a high-level domain-specific language (DSL).

The tough technical challenge we face when designing a DSL for search heuristics, does not lie in designing a high-level syntax; several proposals have already been made. What is really problematic is to bridge the gap between a conceptually simple specification language (high-level, purely functional and naturally compositional) and an efficient implementation (typically low-level, imperative and highly non-modular). This is indeed where existing approaches fail; they restrict the expressiveness of their DSL to face up to implementation limitations, or they raise errors when the user strays out of the implemented subset.

We overcome this challenge with a systematic approach that disentangles different primitive concepts into separate modular *mixin* components, each of which corresponds to a feature in the high-level DSL. The great advantage of mixin components to provide a semantics for our DSL is its modular extensibility.

```

s ::= prune
    prunes the node
  | base_search(...)
    label
  | let(v, e, s)
    introduce new global variable v with initial
    value e, then perform s
  | assign(v, e)
    assign e to variable v and succeed
  | and([s1, s2, ..., sn])
    perform s1, on success start s2 otherwise fail, ...
  | or([s1, s2, ..., sn])
    perform s1, on termination start s2, ...
  | post(c, s)
    perform s and post a constraint c at every node

```

**Fig. 1.** Syntax of Search Heuristics DSL

We can add new features to the language by adding more mixin components. The cost of adding such a new component is small, because it does not require changes to the existing ones.

Here, we focus in particular on heuristics for systematic tree search in the area of Constraint Programming (CP), but the same issues apply to other search-driven areas in the field of Artificial Intelligence (AI) and related areas such as Operations Research (OR). We describe our Haskell implementation of this DSL, where mixin components combine to form a code generator that emits tight C++ code, and in particular cover the memoization challenges in this approach.

## 2 Brief DSL Overview

We provide the user with a high-level domain-specific language (DSL) for expressing search heuristics. For this DSL we use a concrete syntax, in the form of nested terms, that is compatible with the *annotation* language of MiniZinc [7], a popular language for modeling combinatorial problems.

The search specification implicitly defines a search tree whose leaves are solutions to the given problem. Our implementation parses a MiniZinc model, extracts the search specification expressed in our DSL and generates the corresponding low-level C++ code for navigating the search tree. The remainder of the MiniZinc model (expressing the actual combinatorial problem) is shipped to the Gecode library [5], a state-of-the-art finite domain constraint solver. The search code interacts with the solver at every node of the search tree to determine whether a solution or dead end has been reached, or whether to generate new child nodes for further exploration.

## 2.1 DSL Syntax

The DSL’s *expression language* comprises the typical arithmetic and comparison operators and literals that require no further explanation. Notable though is the fact that it allows referring to the constraint variables and parameters of the constraint model.

The DSL’s *search heuristics language* features a number of primitives, listed in the catalog of Fig. 1, in terms of which more complex heuristics can be defined. The catalog consists of both *basic* heuristics and *combinators*. The former define complete (albeit very basic) heuristics by themselves, while the latter alter the behavior of one or more other heuristics.

There are two basic heuristics: **prune**, which cuts the search tree below the current node, and the base search strategies, which implement the *labeling* (also known as *enumeration*) strategies. We do not elaborate on the base search here, because this has been studied extensively in the literature. While only a few basic heuristics exist, the DSL derives great expressive power from the infinite number of ways in which these basic heuristics can be composed by means of combinators.

The combinator **let**( $v, e, s$ ) introduces a new variable  $v$ , initialized to the value of expression  $e$ , in the subsearch  $s$ , while **assign**( $v, e$ ) assigns the value of  $e$  to  $v$  and succeeds. The and-sequential composition **and**( $[s_1, \dots, s_n]$ ) runs  $s_1$  and at every success leaf runs **and**( $[s_2, \dots, s_n]$ ). In contrast, **or**( $[s_1, \dots, s_n]$ ) first runs  $s_1$  in full before restarting with **or**( $[s_2, \dots, s_n]$ ).

Finally, the **post**( $c, s$ ) primitive provides access to the underlying constraint solver, posting a constraint  $c$  at every node during  $s$ . If  $s$  is omitted, it posts the constraint and immediately succeeds.

As an example, this is how branch-and-bound — a typical optimization heuristic — can be expressed in the DSL:

```
let(best, 9999, post(obj < best, and([base_search(...), assign(best, obj)])), )
```

**let** introduces the variable *best*, **post** makes sure the constraint  $obj < best$  is enforced at each node of the search tree spawned by **base\_search**. Combining it with **assign** using **and** causes the *best* variable to be updated after finding solutions. Note that we refer to *obj*, the program variable being minimized.

## 3 Implementation

In this section we cover our Haskell implementation of the DSL, which generates the corresponding low-level imperative C++ code from a high-level functional search specification. We skip the parsing phase and immediately show how we implement the DSL constructs in a modular fashion.

### 3.1 C++ Abstract Syntax Tree

Before we discuss the code generator, we need to define the target language, a C++ AST, which is partly given here:

<b>data</b> <i>Stmt</i> = <i>Nop</i>		<i>Expr</i> := <i>Expr</i>
<i>IfThenElse Expr Stmt Stmt</i>		<i>Stmt</i> ; <i>Stmt</i>
<i>Call String [Expr]</i>		<i>While Expr Stmt</i>
...		

A number of convenient abbreviations facilitate building this AST, e.g.,

$(\S) = \text{liftM} \circ (;$   
 $\text{if}' = \text{liftM2} \circ \text{IfThenElse}$

In our modular code generation approach, AST fragments from different sources are combined. This often leads to incomprehensible (non-idiomatic) code. To make the resulting C++ source code readable, we have implemented a simplifier that is invoked by the pretty printer.

### 3.2 The Code Generator

The C++ AST for a search heuristic is produced by a code generator:

**data** *Gen m* = *Gen* { *init<sub>G</sub>* :: *m Stmt*, *body<sub>G</sub>* :: *m Stmt*  
, *add<sub>G</sub>* :: *m Stmt*, *try<sub>G</sub>* :: *m Stmt*  
, *result<sub>G</sub>* :: *m Stmt*, *fail<sub>G</sub>* :: *m Stmt*  
, *height* :: *Int* }

A code generator consists of a number of hooks that produce the corresponding AST fragments.<sup>5</sup> Code generation may involve side effects; hence *Gen* is parametrized in a monad *m*.

The separate hooks correspond to several stages for the processing of nodes in a search tree. Nodes are initialized with *init<sub>G</sub>* and processed using consecutively *body<sub>G</sub>*, *add<sub>G</sub>*, and *try<sub>G</sub>*. *result<sub>G</sub>* is used for reporting solutions, and *fail<sub>G</sub>* for aborting after failure. The *height* field indicates how high the stack of combinators is.

The fragments of the different hooks are combined according to the following template.

```

gen :: Monad m => Gen m -> m Stmt
gen g = do init <- initG g
          try <- tryG g
          body <- bodyG g
          return $ declarations
                ; init
                ; try
                ; While queueNotEmpty body

```

After emitting a number of variable declarations which we omit due to space constraints, the template creates the root node in the search tree through *init<sub>G</sub>*, and *try<sub>G</sub>* initializes a queue with child nodes of the root. Then, in the main part of the algorithm, nodes in the queue are processed one at a time with the *body<sub>G</sub>* hook.

<sup>5</sup> See Section 3.3 for why we partition the code generation into these hooks

### 3.3 Code Generation Mixins

Instead of writing a monolithic code generator for every different search heuristic, we modularly compose new heuristics from one or more components, each of which corresponds to a constructor in the high-level DSL. Our code generator components are implemented as (functional) mixins [2]:

```
type Mixin  $a \rightarrow a$ 
type MGen  $m = \text{Mixin } (Gen\ m)$ 
```

There are two kinds of mixin components: *base* components that are self-contained, and *advice* components that extend or modify one or more other components.

*Base Component* The main example of a base component is the enumeration strategy *base<sub>M</sub>*:

```
baseM :: Monad  $m \Rightarrow \text{MGen } m$ 
baseM this =
  Gen { initG   = return Nop
        , bodyG  = addG this
        , addG   = constrain ; tryG this
        , tryG   = let ret = resultG this
                      succ = if' isSolved ret doBranch
                      in if' isFailed (failG this) succ
        , resultG = return Nop
        , failG  = return Nop
        , height = 0 }
```

The above code omits details related to posting constraints (*constrain*), checking the solver status (*isSolved* or *isFailed*) and branching (*doBranch*). The details of these operations depend on the particular constraint solver involved (e.g. finite domain, linear programming, ...); here we focus only on the search heuristics, which are orthogonal to those details.

As we can see the base component is parametrized by *this*, the overall search heuristic. This way, the *base<sub>M</sub>* search can make the final call to *body<sub>G</sub>* redirect to a *add<sub>G</sub>* on the top of the combinator-stack again, and similarly for *add<sub>G</sub>* and *try<sub>G</sub>*.

The simplest form of a search heuristic is obtained by applying the fixpoint combinator to a base component:

```
fix :: Mixin  $a \rightarrow a$ 
fix  $m = m\ (fix\ m)$ 
search1 :: Gen Identity
search1 = fix baseM
```

*Advice Component* The mixin mechanism allows us to plug in additional advice components before applying the fixpoint combinator. This way we can modify the base component's behavior.

Consider a simple example of an advice combinator that prints solutions:

```
printM :: Monad m ⇒ MGen m
printM super = super { resultG = printSolution ; resultG super
                      , height = 1 + height super }
```

where *printSolution* consists of the necessary solver-specific code to access and print the solution. A code generator is obtained through mixin composition, simply using ( $\circ$ ):

```
search2 :: Gen Identity
search2 = fix (printM ∘ baseM)
```

### 3.4 Monadic Components

In the components we have seen so far, the monad type parameter  $m$  has not been used. It does become essential when we turn to more complex components such as the binary conjunction `and`( $[s_1, s_2]$ ).

The code presented at the end of this section shows a simplified *and* combinator, for two *Gen m* structures with the same type  $m$ . It does require  $m$  to be an instance of *MonadState Side*, to store the current branch at code-generation runtime. While some hooks simply dispatch to the corresponding hook of the currently active branch, *body<sub>G</sub>* and *result<sub>G</sub>* are more elaborate.

First of all, we also need to store the branch number at program runtime. This is known at the time when the node is created, but needs to be restored into the monadic state when activating it. We assume the functions *store* and *retrieve* give access to a runtime state for each node, indexed with a field name and the height of the combinator involved.

When the *result<sub>G</sub>* hook is called — implying a solution for a sub-branch was found — there are two options. Either the  $s_1$  was active, in which case both the runtime state and the monadic state are updated to *In2*, and *init<sub>G</sub>* and *try<sub>G</sub>* for  $s_2$  are executed, which will possibly cause the node to be added to the queue, if branching is required. When this new node is activated itself, its *body<sub>G</sub>* hook will be called, retrieving the branch information from the runtime state, and dispatching dynamically to  $s_2$ . When a solution is reached after switching to  $s_2$ , *result<sub>G</sub>* will finally call  $s_2$ 's *result<sub>G</sub>* to report the full solution.

```
data Branch = In1 | In2
type Mixin2 a = a → a → a
andM :: MonadState Branch m ⇒ Mixin2 (Gen m)
andM g1 g2 = Gen { initG   = store myHeight "pos" In1 ; initG g1
                  , addG    = dispatch addG
                  , tryG    = dispatch tryG }
```

```

, failG = dispatch failG
, bodyG = myBody
, resultG = myResult
, height = myHeight }
where parent = get ≫ λx → case x of
    In1 → return g1
    In2 → return g2
dispatch f = parent ≫ f
myHeight = 1 + max (height g1) (height g2)
myBody = let pos = retrieve myHeight "pos"
    br1 = modify (const In1) ≫ (bodyG g1)
    br2 = modify (const In2) ≫ (bodyG g2)
    in if' (pos := In1) br1 br2
myResult = do num ← get
    case num of
        In1 → modify (const In2) ≫
            store myHeight "pos" In2
            § liftM2 (:) (initG g2) (tryG g2)
        In2 → resultG g2

```

### 3.5 Effect Encapsulation

So far we have parametrized *MGen* with  $m$ , a monad type parameter. This parameter will have to be assembled appropriately from monad transformers to satisfy the need of every mixin component in the code generator. Doing this manually can be quite cumbersome. Especially for a large number of mixin components with multiple instances of, e.g., *StateT* this becomes impractical. To simplify the process, we turn to a technique proposed by Schrijvers and Oliveira [8] to encapsulate the monad transformers inside the components.

```

data Search = ∀ t2. MonadTrans t2 ⇒
    Search { mgen :: ∀ m t1. (Monad m, MonadTrans t1) ⇒ MGen ((t1 ▷ t2) m)
    , run    :: ∀ m x. Monad m ⇒ t2 m x → m x }

```

To that end we now represent components by *Search*, which packages the components behavior *MGen* with its side effect  $t_2$ . The monad transformer  $t_2$  is existentially quantified to remain hidden; we can eliminate it from a monad stack with the *run* field. The hooks of the component are available through the *mgen* field, which specifies them for an arbitrary monad stack in which  $t_2$  is surrounded by more effects  $t_1$  above and  $m$  below. Here  $t_1 \triangleright t_2$  indicates that the focus rests on  $t_2$  (away from  $t_1$ ) for resolving overloaded monadic primitives such as *get* and *put*, for which multiple implementations may be available in the monad stack. We refer to [9,8] for details of this focusing mechanism, known as the *monad zipper*.

An auxiliary function promotes a non-effectful *MGen*  $m$  to *MSearch*:

```

type MSearch = Mixin Search
mkSearch :: ( $\forall m. \text{Monad } m \Rightarrow \text{MGen } m$ )  $\rightarrow$  MSearch
mkSearch f super =
  case super of
    Search { mgen = mgen, run = run }  $\rightarrow$  Search { mgen = f  $\circ$  mgen
                                                    , run = run }

```

which we can apply for instance to  $\text{base}_M$  and  $\text{print}_M$ .

```

baseS, printS :: MSearch
baseS = mkSearch baseM
printS = mkSearch printM

```

Similarly, we define  $\text{mkSearch}_2$  for lifting binary combinators like  $\text{and}_M$ . It takes a combinator for two  $\text{Gen } m$ 's, as well as a run function for additional monad transformers the combinator may require, and lifts it to  $\text{MSearch}_2$  (implementation omitted).

```

type MSearch2 = Mixin2 Search
andS :: MSearch2
andS = mkSearch2 andM (flip evalStateT In1)
mkSearch2 :: MonadTrans t2
            $\Rightarrow$  ( $\forall m. t_1. (\text{Monad } m, \text{MonadTrans } t_1) \Rightarrow \text{Mixin}_2 (\text{Gen } ((t_1 \triangleright t_2) m)))$ 
            $\rightarrow$  ( $\forall m. x. \text{Monad } m \Rightarrow t_2 m x \rightarrow m x$ )
            $\rightarrow$  MSearch2

```

Finally we produce C++ code from a  $\text{Search}$  component with  $\text{generate}$ :

```

generate :: Search  $\rightarrow$  Stmt
generate s = case s of
  Search { mgen = mgen, run = run }  $\rightarrow$ 
    runIdentity $ run $ runIdentityT $ runZ $ gen $ fix $ mgen

```

This code first applies the fixpoint computation, passing the result back into itself, as explained earlier. After that,  $\text{gen}$  is called to get the real code-generating monad action. it extracts the knot-tied  $\text{body}_G$  hook,  $\text{runZ}$  eliminates  $\triangleright$  from  $(t_1 \triangleright t_2) m$ , yielding  $t_1 (t_2 m)$ . Then  $\text{runIdentityT}$  eliminates  $t_1$  (instantiating it to be  $\text{IdentityT}$ ),  $\text{run}$  eliminates  $t_2$ , and  $\text{runIdentity}$  finally eliminates  $m$  (instantiating it to be  $\text{Identity}$ ) to yield a  $\text{Stmt}$ .

## 4 Memoization and Inlining

Experimental evaluation indicates that several component hooks in a complex search heuristic are called frequently, as for example the  $\text{fail}_G$  hook can be called from many different places. This is a problem 1) for the code generation — which needs to generate the corresponding code over and over again — and 2) for the generated program which contains much redundant code. Both significantly impact the compilation time (in Haskell and in C++); in addition, an overly large binary executable may adversely affect the cache and ultimately the running time.

#### 4.1 Basic Memoization

A well-known approach that avoids the first problem, repeatedly computing the same result, is *memoization*. Fortunately, Brown and Cook [3] have shown that memoization can be added as a monadic mixin component without any major complications.

Memoization is a side effect for which we define a custom monad transformer:

```
newtype  $\mathbb{M}_T m a = \mathbb{M}_T \{ \text{run} \mathbb{M}_T :: \text{StateT Table } m a \}$ 
deriving (MonadTrans)
runMemoT :: Monad m  $\Rightarrow \mathbb{M}_T m a \rightarrow m (a, \text{Table})$ 
runMemoT m = runStateT (run $\mathbb{M}_T$  m) initMemoState
```

which is essentially a state transformer that maintains a table from *Keys* to *Stmts*. For now we use *Strings* as *Keys*.

```
newtype Key = String
newtype Table = Map Key Stmt
initMemoState = empty
```

We capture the two essential operations of  $\mathbb{M}_T$  in a type class, which allows us to lift the operations through other monad transformers.<sup>6</sup>

```
class Monad m  $\Rightarrow \mathbb{M}_M m$  where
  getM :: String  $\rightarrow m (\text{Maybe Stmt})$ 
  putM :: String  $\rightarrow Stmt \rightarrow m ()$ 
instance Monad m  $\Rightarrow \mathbb{M}_M (\mathbb{M}_T m)$  where ...
instance ( $\mathbb{M}_M m, \text{MonadTrans } t$ )  $\Rightarrow \mathbb{M}_M (t m)$  where ...
```

These operations are used in an auxiliary mixin function:

```
memo ::  $\mathbb{M}_M m \Rightarrow \text{String} \rightarrow \text{Mixin } (m \text{ Stmt})$ 
memo s m = do stm  $\leftarrow$  getM s
case stm of
  Nothing  $\rightarrow$  do code  $\leftarrow$  m
               putM s code
               return code
  Just code  $\rightarrow$  return code
```

which is used by the advice component:

```
memo_M ::  $\mathbb{M}_M m \Rightarrow \text{MGen } m$ 
memo_M super = super { init_G = memo "init" (init_G super)
                      , body_G = memo "body" (body_G super)
                      , add_G = memo "add" (add_G super)
                      , try_G = memo "try" (try_G super) }
```

---

<sup>6</sup> For lack of space we omit the straightforward instance implementations.

```
, resultG = memo "result" (resultG super)
, failG   = memo "fail"   (failG   super)}
```

which allows us to define, e.g., a memoized variant of *print<sub>S</sub>*.

```
printS = mkSearch (memoM ∘ printM)
```

Note that in order to lift *memo<sub>M</sub>* to a *Search* structure, *Search* must be updated with a  $\mathbb{M}_M$  *m* constraint, and *generate* must be updated to incorporate *runMemoT* in its evaluation chain.

```
data Search = ∀ t2. MonadTrans t2 ⇒
  Search { mgen :: ∀ m t1. (ℳM m, MonadTrans t1) ⇒ MGen ((t1 ▷ t2) m)
        , run   :: ∀ m x. ℳM m ⇒ t2 m x → m x }
generate s =
  case s of
    Search { mgen = mgen, run = run } →
      runIdentity $ runMemoT $ run $ runIdentityT $ runZ $ gen $ fix mgen
```

## 4.2 Monadic Memoization

Unfortunately, it is not quite this simple. The behavior of combinator hooks may depend on internal updateable state. The above memoization does not take this state dependency into account.

In order to solve this issue, we must expose the components' state to the memoizer. This is done in two steps. First,  $\mathbb{M}_T$  keeps a *context* in addition to the memoization table, and provides access to it through the  $\mathbb{M}_M$  type class. Second — for the specific case of a *StateT s* with *s* an instance of *Showable* — an alternative implementation (*MemoStateT*) which updates the context in the  $\mathbb{M}_T$  layer below it, is provided.

To implement this, the *Table* type is extended:

```
type MemoContext = Map Int String
type Key         = (MemoContext, String)
data Table = Table { context :: MemoContext
                    , memoMap :: Map Key Stmt }
initMemoState = Table { context    = empty
                      , memoMap    = empty }
```

*MemoContext* is represented as a map from integers to strings. The integers are identifiers assigned to the monad transformer layers that have context, and the strings are serialized versions of the contextual data inside those layers (using *show*).

The  $\mathbb{M}_M$  type class is extended to support modifying the context information, using *setCtx* and *clearCtx*.

```
class Monad  $m \Rightarrow \mathbb{M}_M m$  where
```

```
...
setCtx :: Int → String → m ()
clearCtx :: Int → m ()
```

Finally,  $\mathbb{MS}_T$  is introduced. It will contain a wrapped *ReaderT* and *StateT*-transformed monad. The state will be stored in the *StateT*, while the *ReaderT* is used to give access to the identifier of the layer.

```
newtype  $\mathbb{MS}_T s m a = \mathbb{MS}_T \{ \text{runMS}_T :: \text{ReaderT Int (StateT s m) } a \}$ 
```

For convenience,  $\mathbb{MS}_T$  is made an instance of *MonadState*, so switching from *StateT* to  $\mathbb{MS}_T$  does not require any changes to the code interacting with it.

When running a  $\mathbb{MS}_T$  transformer, the enclosing *Gen*'s *height* parameter is passed to *rStateT*, using that as identifier for the layer. The runtime state itself is stored inside the wrapped *StateT* layer, while a serialized representation (using *show*) is stored in the context of the underlying  $\mathbb{M}_T$ .

```
instance (Show s,  $\mathbb{M}_M m$ )  $\Rightarrow$  MonadState s ( $\mathbb{MS}_T s m$ ) where
```

```
get  =  $\mathbb{MS}_T$  get
put s =  $\mathbb{MS}_T$  $ do n ← ask
              putCtx n (show s)
              put s
```

```
rStateT :: ( $\mathbb{M}_M m$ , Show s)  $\Rightarrow$  s → Int →  $\mathbb{MS}_T s m a \rightarrow m a$ 
rStateT s height m =
```

```
  do let action = runReaderT (run $\mathbb{MS}_T$  m) height
      putCtx height (show s)
      result ← evalStateT action s
      clearCtx height
      return result
```

### 4.3 Backend Sharing

So far we have only solved the first performance problem, repeated generation of code. Memoization avoids the repeated execution of hooks by storing and reusing the same C++ code fragment. However, the second performance problem, repeated use of the same C++ code, remains.

We preserve the sharing obtained through memoization in the backend, by depositing the memoized code fragment in a C++ function that is called from multiple sites. Conceptually, this means that a memoized hook returns a function call (rather than a potentially big code fragment), and produces a function definition as a side effect.<sup>7</sup>

<sup>7</sup> The function *getFnName* — given without implementation — derives a unique function name for a given code fragment.

```

memo2 :: MM m ⇒ String → Mixin (m Stmt)
memo2 s m = do code ← memo s m
             let name = getFnName code
             return (Call name [])

getFnName :: Stmt → String

```

The following *generate* function produces both the main search code and the auxiliary functions for the memoized hooks. By introducing *runMemoT* in the chain of evaluation functions, the types change, and the result will be of type *(Stmt, Table)*, since that is returned by *runMemoT*.

```

data FunDef = FunDef String Stmt
toFunDef :: Stmt → FunDef
toFunDef stm = FunDef (getFnName stm) stm
generate :: Search → (Stmt, [FunDef])
generate s =
  case s of
    Search { mgen = mgen, run = run } →
      let eval      = fix mgen
          codeM      = gen eval
          memoM      = run ∘ runIdentityT ∘ runZ $ codeM
          (code, state) = runIdentity $ runMemoT memoM
      in (code, map toFunDef ∘ elems $ memoMap state)

```

Note that only code generated by the same hook of the same component is shared in a function, not code of distinct hooks or distinct components. Detecting such unrelated *clones* would slow down rather than speed up the code generation process.

Finally, applying the above technique systematically results in one generated C++ function per component hook. This is not entirely satisfactory, as many memoized functions are only called once, or only contain a single line of code. One can either rely on the C++ compiler to determine when inlining is lucrative, or perform inlining on the C++ AST in an additional processing step.

## 5 Evaluation

In this section, we evaluate our Haskell implementation that we have described in the previous sections. We have omitted a number of complicating factors in our account, so as not to distract from the main issues. Without going into detail, we list the main differences with the actual implementation:

- There are more hooks, including ones called during branching, adding to the queue, deletion of nodes and switching between nodes belonging to separate strategies. Furthermore, additional hooks exist for the creation of combinator-specific data structures, both globally for the whole combinator, or locally for each node, instead of the dynamic *height*-based mechanism.

- The code generation hooks are functions that take an additional argument, the *path info*. It contains which variable names point to the local and global data structures, which variables need to be passed to generated memoized functions, and pieces of code that need to be executed when the current node needs to be stored, aborted or copied. The values in the path info are also taken into account when memoizing, complicating matters further.
- We have built into the code generators a number of optimizations. For example, knowing that combinators never branch, allows omitting generated code and data structures.
- Searches keep track of whether they complete exhaustively, or are pruned. Repeat-like combinators use exhaustiveness as an additional stop criterion.

To evaluate the usefulness of our system, benchmarks<sup>8</sup> were performed (see Table 1)<sup>9</sup>. A first set includes the known problems **golfers**<sup>10</sup>, **golomb**<sup>11</sup>, **open stacks** and **radiation**[1], a second set contains artificial tests.

The first three columns give the name, problem size and whether or not the memoizing version was used. Further columns show the number of generated C++ lines (col. 4), the number of invoked hooks (col. 5), the number of monad transformers active (both the effective ones (col. 6), and including *IdentityT* and  $\triangleright$  (col. 7)). Finally, the average generation (Haskell, col. 8), build (gcc, col. 9) and run time (col. 10) are listed. All these numbers are averages over many runs (of up to an hour of runtime).

For the larger problem instances, memoization reduces both generation time and build time, by reducing the number of generated lines. Performance is not affected by the increased number of function calls — perhaps compensated by the improved cache usage of smaller code. In particular for the **radiation** example, the effect of memoization is drastic. On the other hand, for small problems, memoization does not help, but the overhead is very small.

## 6 Related Work

We were inspired by the monadic mixin approach to memoization of Brown and Cook [3]. However, they only address memoization for non-effectful components. Although mentioning the problem, they do not provide a solution for memoizing stateful components. In our setting we are forced to address this problem and do so by also memoizing the implicit state.

A different approach that results in smaller code generated from a DSL is *observable sharing* [4,6]. Yet, the main intent of observable sharing is quite different. Its aim is to preserve sharing at the level of Haskell in the resulting

**Table 1.** Benchmark results

generated code, typically using *unsafePerformIO*. It does not detect distinct calls that result in the same code, and is hard to integrate with code-generating monadic computations as appear in our setting.

Our work is directly inspired by earlier work on the Monadic Constraint Programming DSL [10,12]. In particular, we have studied how to compile high-level problem specifications in Haskell to C++ code for the Gecode library [11]. The present complements this with high-level search specifications.

## 7 Conclusions

We have shown how to implement a code generator for declarative specification of a search heuristic using monadic mixins. This mixin-based approach, search combinators can be implemented in a modular way, and still independently modify the behavior of the generated code. Through existential types and the monad zipper, all combinators can introduce their own monad transformers

to keep their own state throughout the code generation, without affecting any other transformers.

Since the naive approach leads to certain hooks being invoked many times over, we turn to memoization to avoid code duplication. Memoization is implemented as another monadic mixin which is added transparently to existing combinators.

The system is implemented as a Haskell program that generates search code in C++ from a search specification in MiniZinc which is then further integrated in a CP solver (Gecode). Our benchmarks demonstrate the impact of memoizing the monadic mixins.
